Using the co-located seismic and pressure data from the USArray Transportable Array, we analyzed the effects of surface pressure changes on seismic noise generation. We show in the low frequency band (0.01-0.02 Hz) that vertical seismic noise can be modelled by the formula $S_z = A*S_p + e_z$ and the horizontal seismic noise by $S_h = B*S_p + e_h$ where $S_z$, $S_h$ and $S_p$ are the power spectral densities (PSD) of vertical ground velocity, horizontal ground velocity and surface pressure. The coefficients $A$ and $B$ are functions of elasticity in the medium and the pressure-wave speed on the surface and $e_z$ and $e_h$ are constant noise terms that are independent of local pressure changes. For the frequency range of our analysis (0.01-0.02 Hz), the horizontal data are dominated by ground tilt.

We found that the horizontal constant noise term can change seasonally for many stations and sometimes create separate branches in the pressure-seismic plots. This may explain why some seismic-noise reduction approaches for horizontal data, by use of a co-located pressure sensor, do not necessarily work well while it seems to work well for vertical seismic data.

We show that shallow rigidity structure in the upper 50-100 m of the Earth can be derived reliably through the determination of the coefficients $A$ and $B$ in the above formulas. Pressure-wave speed on the surface is also derived in the modelling process but its relation to wind speed remains unclear.

We advocate that the co-located pressure and seismic sensors are a powerful tool to gain new insights into the nature of seismic noise.
