The AQABA (Air Quality and climate change in the Arabian BAsin) ship campaign in summer 2017 followed a route from the Mediterranean through the Indian Ocean to the Arabian Gulf. We present a chemical analysis of NO$_x$ and NO$_y$ obtained using Thermal Dissociation Cavity Ringdown Spectroscopy (TD-CRDS).

From the difference between NO$_x$ and NO$_y$, we derive NO$_x$, which can be considered to sequester NO$_x$. This value is not directly influenced by local NO$_x$ emissions and thus allows the identification of longer term trends. The observed NO$_x$ mixing ratios (5 minute averages) ranged from 0.3 ppbv in the Indian Ocean to 7.0 ppbv in the Arabian Gulf. As expected, NO$_x$ shows a higher variability from below 0.1 ppbv in the Indian Ocean to 49.3 ppbv on the approach to the Djibouti harbour area.

The partitioning of NO$_y$ between NO$_x$, organic nitrates, nitric acid and particulate nitrate showed great variability due to the regional influence of megacities, international shipping, petrochemical activity, desert dust and maritime background air. We use the NO$_x$/NO$_y$ ratio to explore the chemical aging of NO$_x$ emissions during transport and support this analysis with formaldehyde and SO$_4^{2-}$/SO$_2$ measurements. From the correlation between odd oxygen ($O_x = O_3 + NO_2$) and NO$_x$, we calculate the ozone production efficiency of NO$_x$ for different parts of the cruise and identify the underlying chemical processes that control O$_3$ formation.
