The first results of a detailed study of $^{137}\text{Cs}$ and $^{90}\text{Sr}$ distribution in elementary landscape-geochemical system (the top-slope-closing depression type, ELGS) are presented on the example of test sites located in the head zone of the East Ural Radioactive Trace formed during the Kyshtym accident in 1957. Field measurements were performed using modified Violinist-III field gamma-spectrometer [1] and the Kolibri spectrometric complex [2]; laboratory determination of $^{137}\text{Cs}$ was made by Canberra gamma-spectrometer (HPGe detector). Field measurements were carried out along cross-sections and in a grid manner with a step of 1 and 5 m accompanied by a theodolite survey and soil core sampling at the selected points. The instrumental layer-by-layer determination of $^{90}\text{Sr}$ activity in soil samples performed in field conditions by [2] was compared with the radiochemical measurement of the same samples in fractions of less than and more than 1 mm. The correlation between the obtained instrumental and radiochemical values for $^{90}\text{Sr}$ activity equaled to $r = 0.962$ ($n = 50$). Spatial distribution of both $^{137}\text{Cs}$ and $^{90}\text{Sr}$ manifested itself in an specifically organized polycentric structure. Against the absence of a pronounced tendency for unidirectional redistribution of radionuclides from the top to the bottom, there was an ordered cyclic change in the activity of both $^{137}\text{Cs}$ and $^{90}\text{Sr}$, which in our opinion reflected the unified mechanism of redistribution of substances in ELGS, where the relief is the main controller of water migration. Measurement of $^{90}\text{Sr}$ activity in selected meadow plants proved an important role of species in radionuclide accumulation at the ELGS level: the maximum amount of $^{90}\text{Sr}$ was found in nettle ($\text{Urtica dioica}$, $86 \pm 19$ kBq/kg dw, $n = 9$), the minimum - in bluegrass ($\text{Poa sp.}$, $13.8 \pm 1.2$ kBq/kg dw, $n = 19$). The revealed features of spatial structure of $^{137}\text{Cs}$ and $^{90}\text{Sr}$ are believed to mark the general tendencies of substances redistribution in ELGS, which seems important for studying soil formation, environmental monitoring and optimization of soil fertilizing.

The study was supported by the RFBR grant No. 19-05-00816.
