session - POSTER

# Introduction (1)

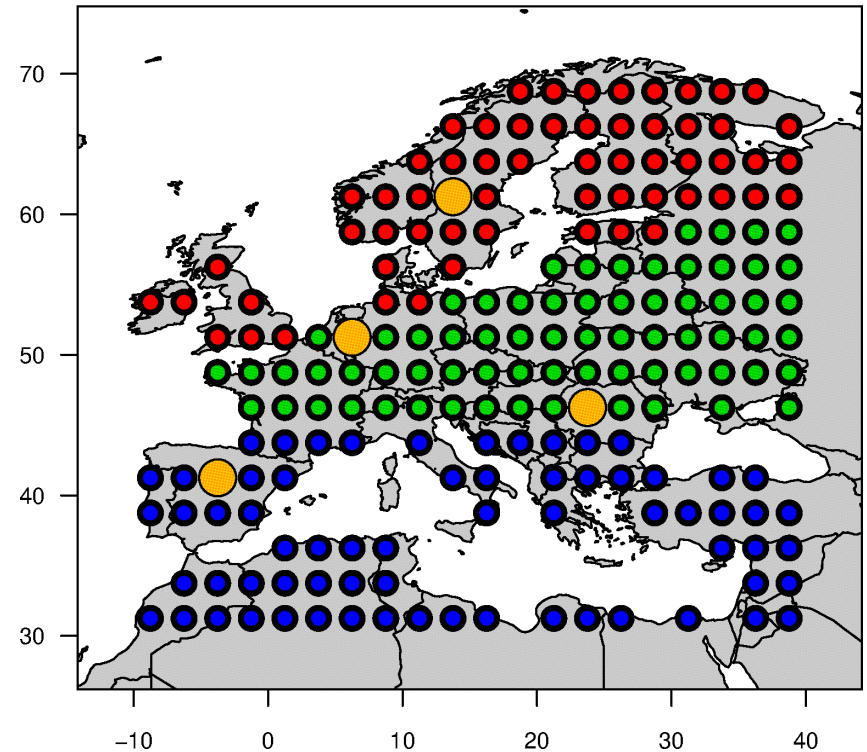

- CP-RCMs are state of the art, but they have one drawback. They are quite **expensive**! Typical simulations are only O(10) years
- **Therefore internal variability (INT)** plays a role in these ‘short’ simulations and influences the derived climate-change signal. **The question is, to what extent? E.g. what is INT at e.g. 10-year time scale when you have only one 10-year simulation?**
- Reducing effect of internal variability in cc signal. Options:
  - **Long separation between REF & FUT periods & scaling**
  - **Aggregation and/or spatial pooling**
  - Try to compute amplitude of INT <= The aim of today’s presentation

# Introduction (2)

- Estimate the amplitude of internal variability (INT) at various time scales
- Ideally, the approach can be used with a single member, and converges to the 'truth' as more and more members are added
- Ideally, the method is compatible with the time-slice approach of the CP-RCM

# Introduction (3)

- Data: 16-member ensemble of 1950-2100 GCM/RCM simulations obtained with EC-Earth/RACMO (certain decades of certain members have been downscaled with the CP-RCM HCLIM-AROME)
- Domains. EUCP WP2 domains (Brunner et al 2020)
  - SREX: MED, CEU, NEU
  - Individual 2.5deg grids

# Approach to compute INT

- INT = ensemble spread at different time scales
- For time scale  $n$  in (1,2,...,50):
  - Compute sliding  $n$ -season averages of precipitation for all members and also for the ensemble mean
  - Take relative differences w.r.t the forced signal  
Assumption: forced signal = loess(ensmean)
  - Compute sd of anoms over all steps (p95-p05  $\sim 3.3\text{sd}$ )

=> The result is a measure of the amplitude of the internal variability at that time scale (Q: or would one call this twice the internal variability?)

# Example: JJA precip (srex MED)

MED = SREX Mediterranean

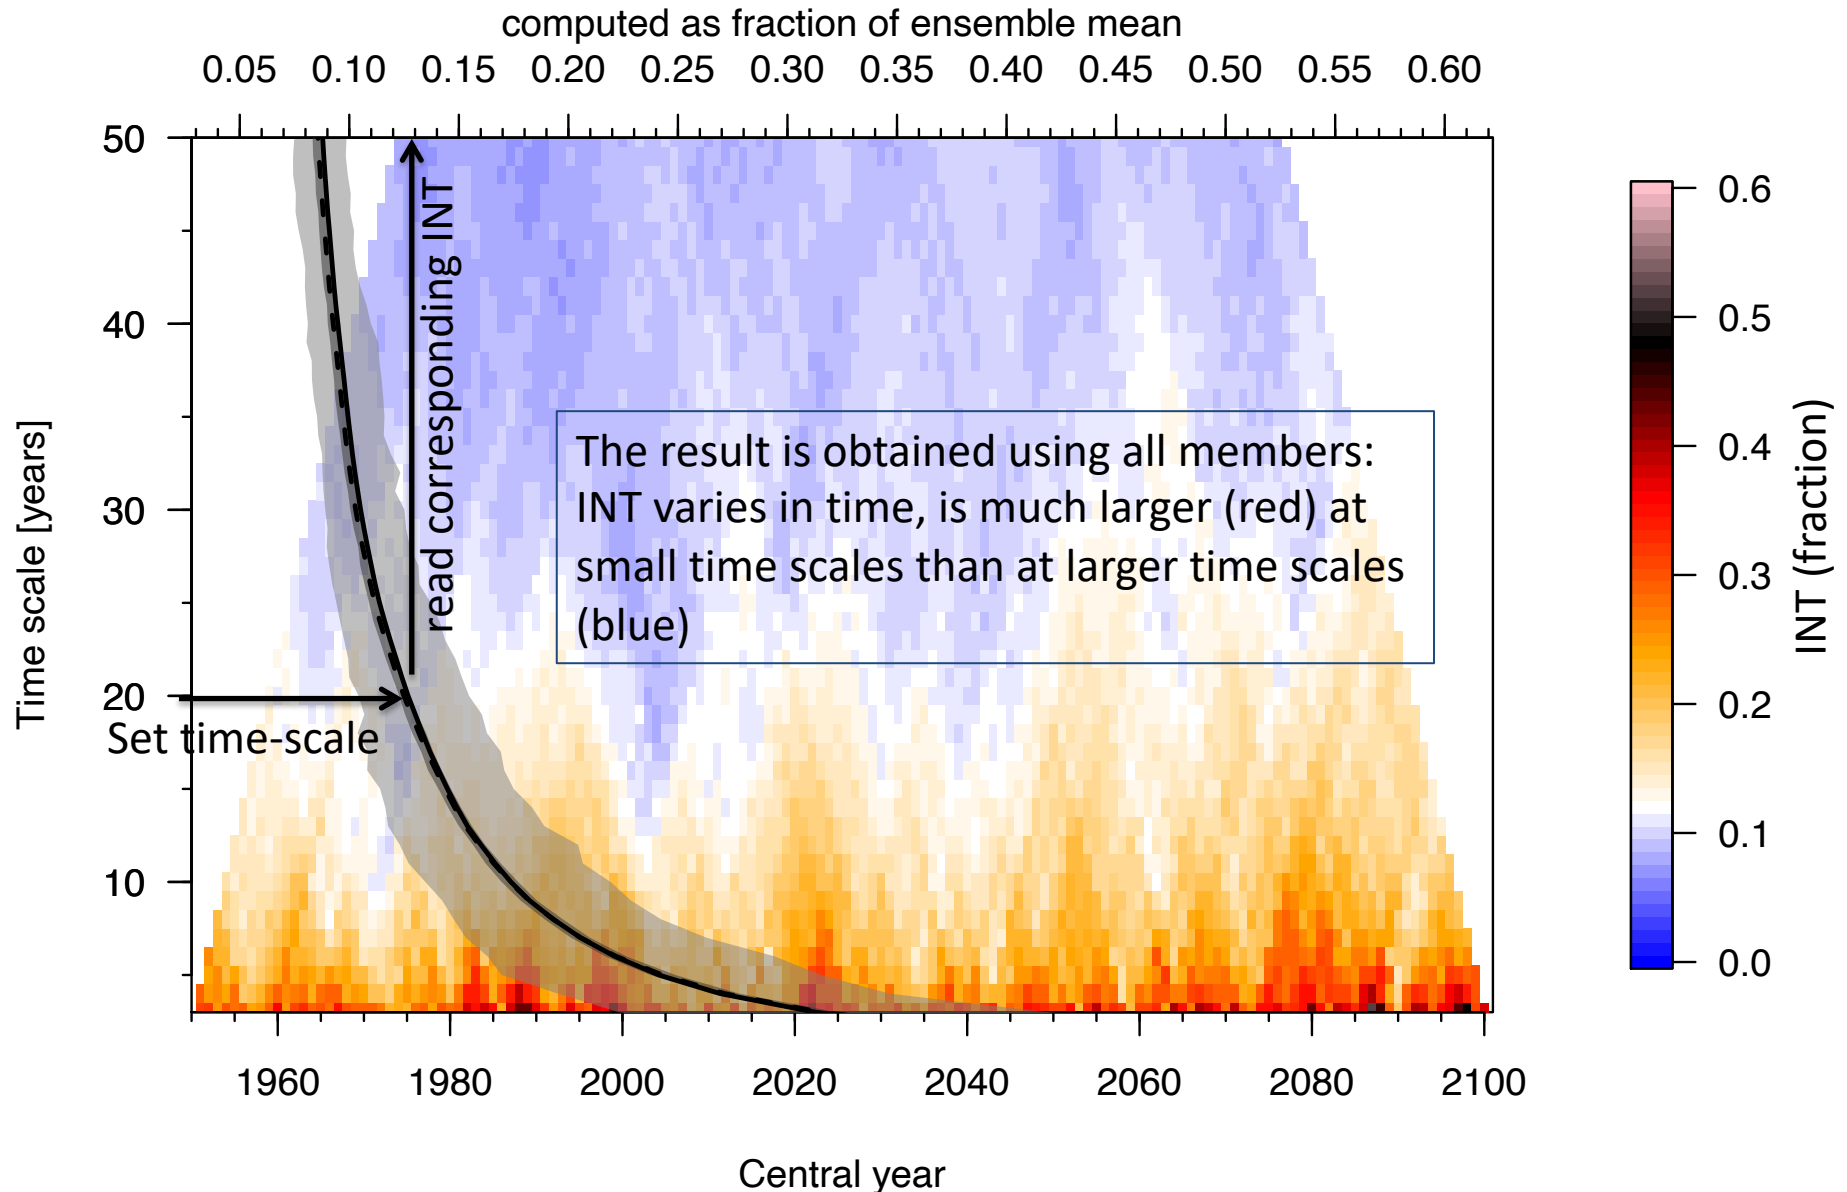

For plotting: JJA season data is first scaled (units of JJA sd).

Here computed for only two members (#1 en 2)

Now we can display INT (range of deviations) in a contour plot

# Example: DJF precip MED

Internal variability for different time-scales  
DJF precip domain: SREX[MED]

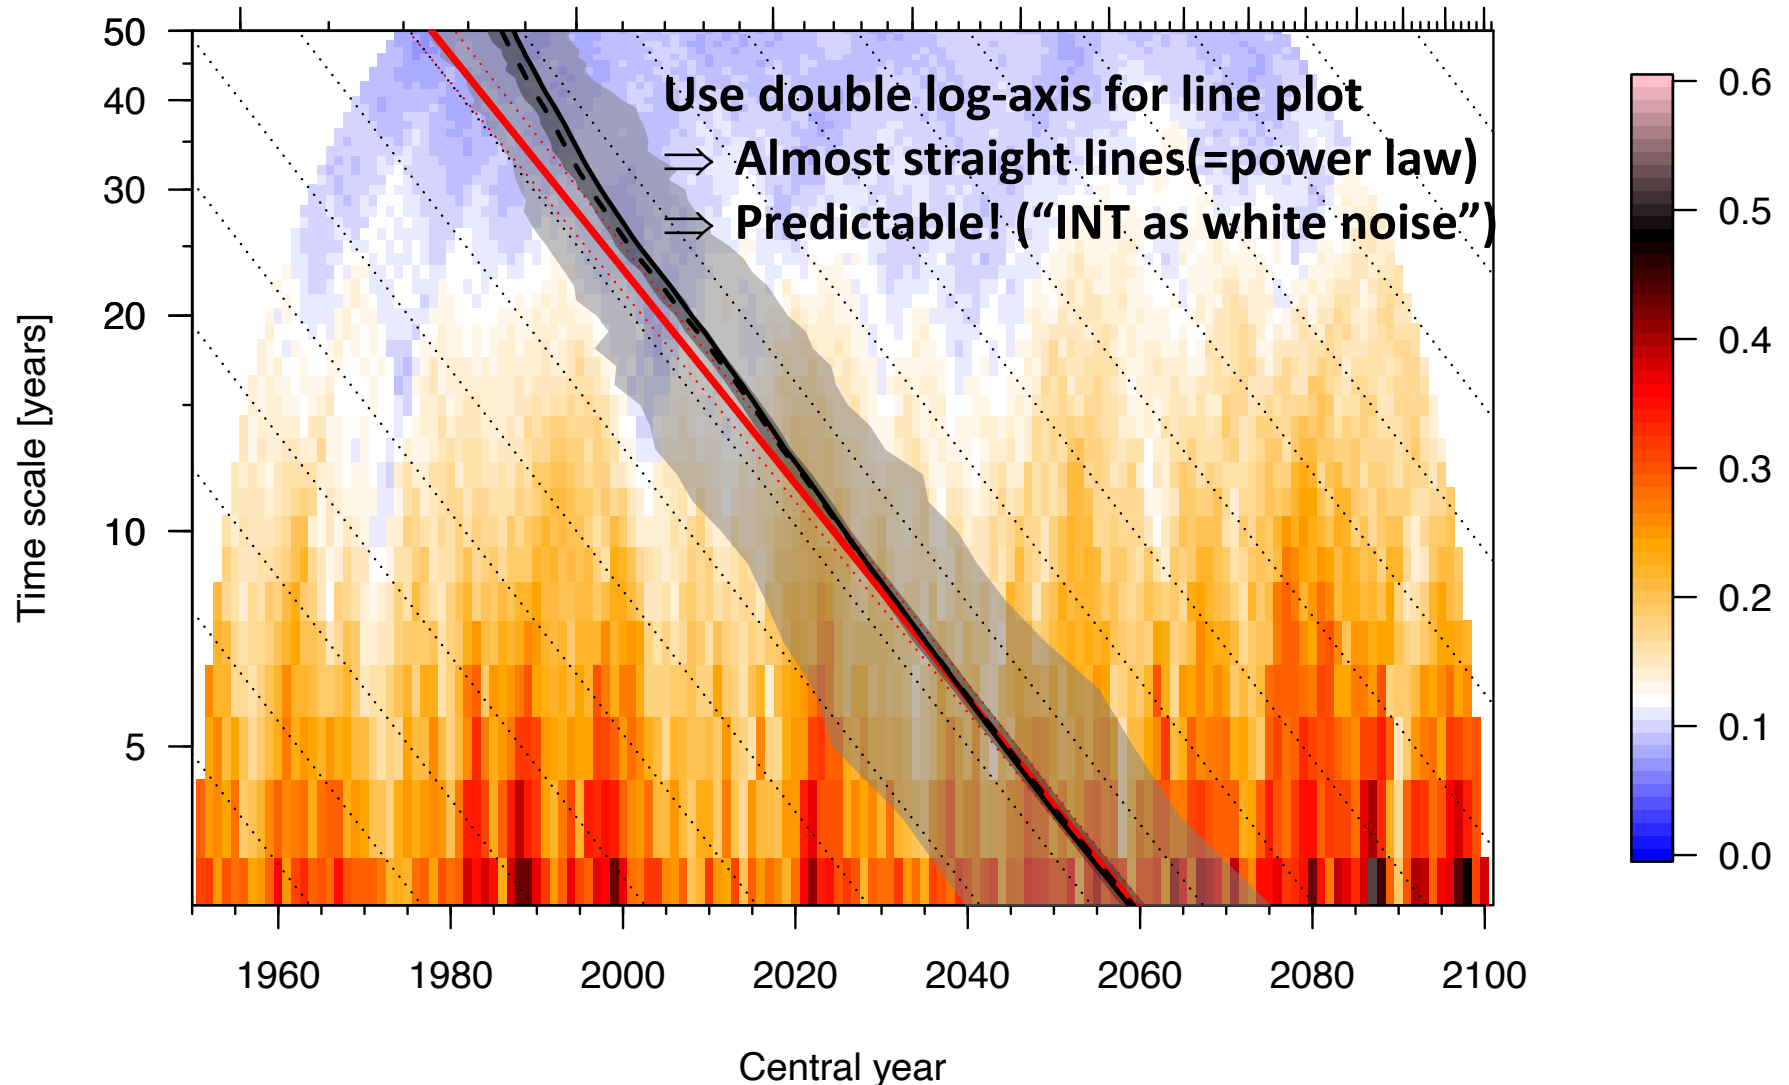

# Now use LOG-scales

## DJF precip MED

Internal variability for different time-scales  
DJF precip domain: SREX[MED]

computed as fraction of ensemble mean

0.05 0.10 0.15 0.20 0.25 0.35 0.45 0.60

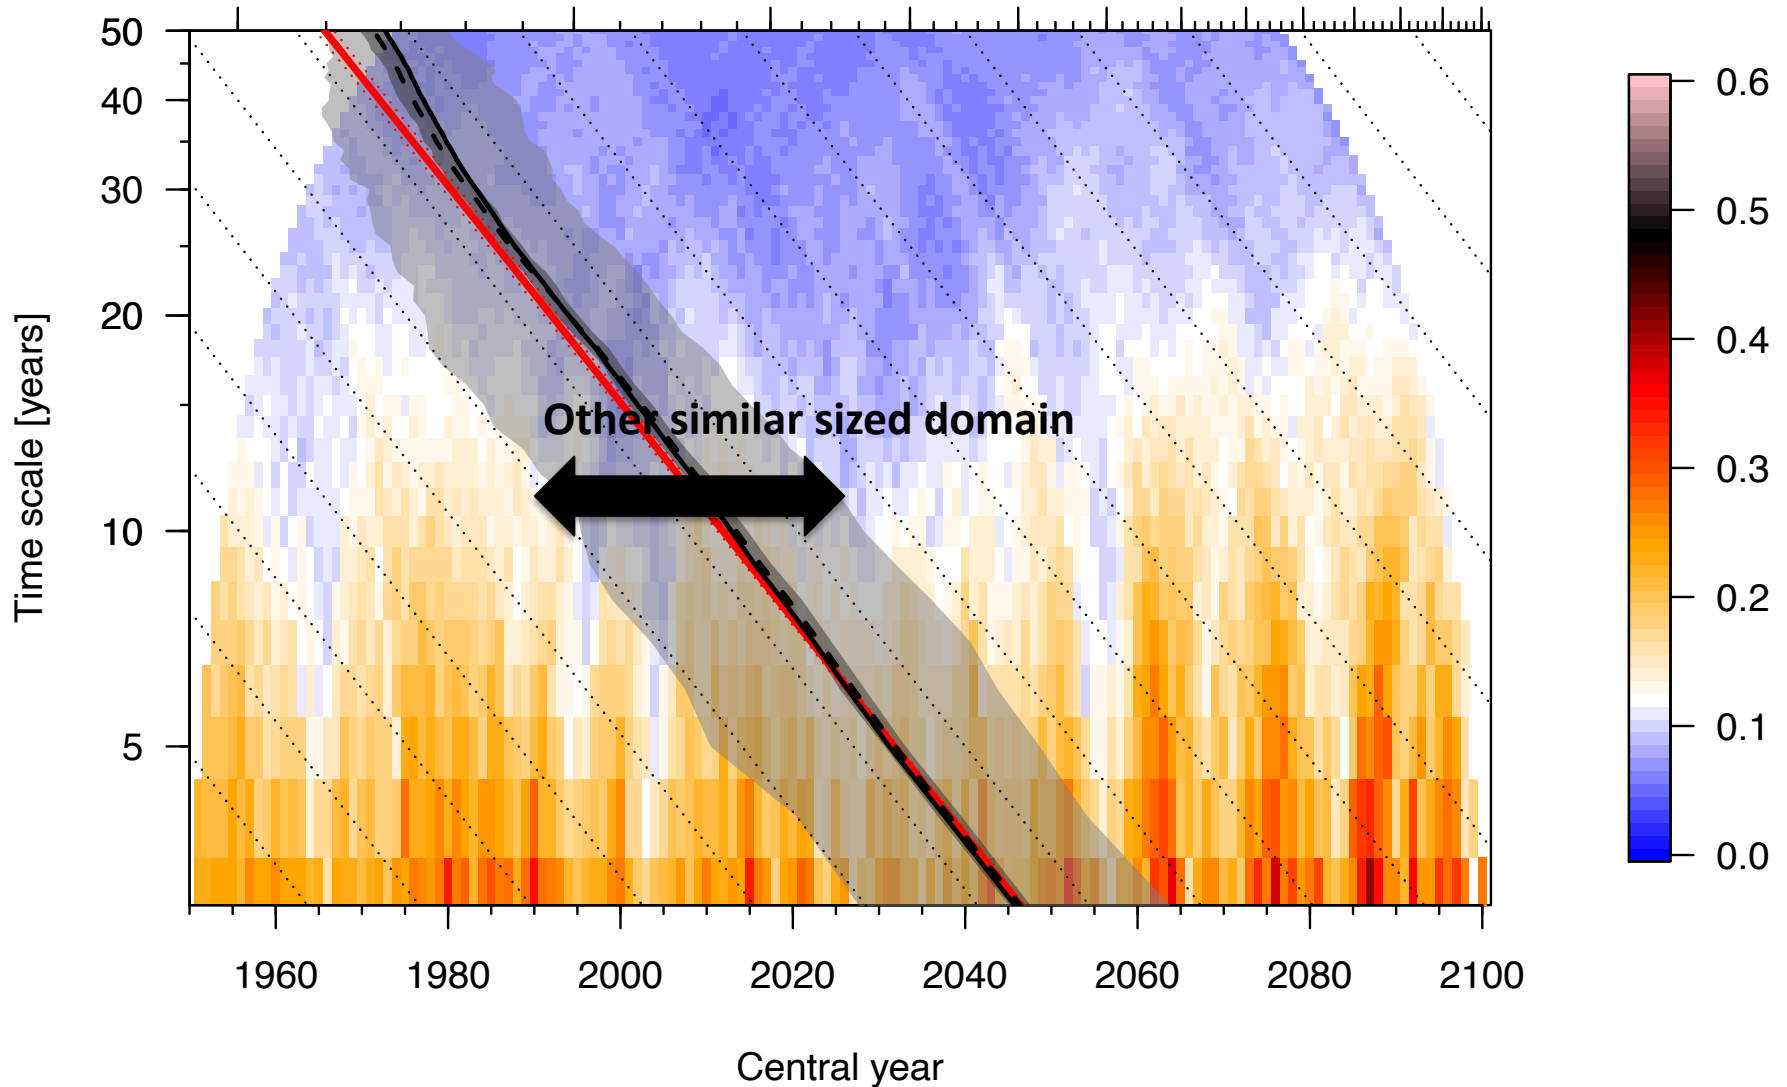

# Other domain NEU

Internal variability for different time-scales  
DJF precip domain: SREX[NEU]

computed as fraction of ensemble mean

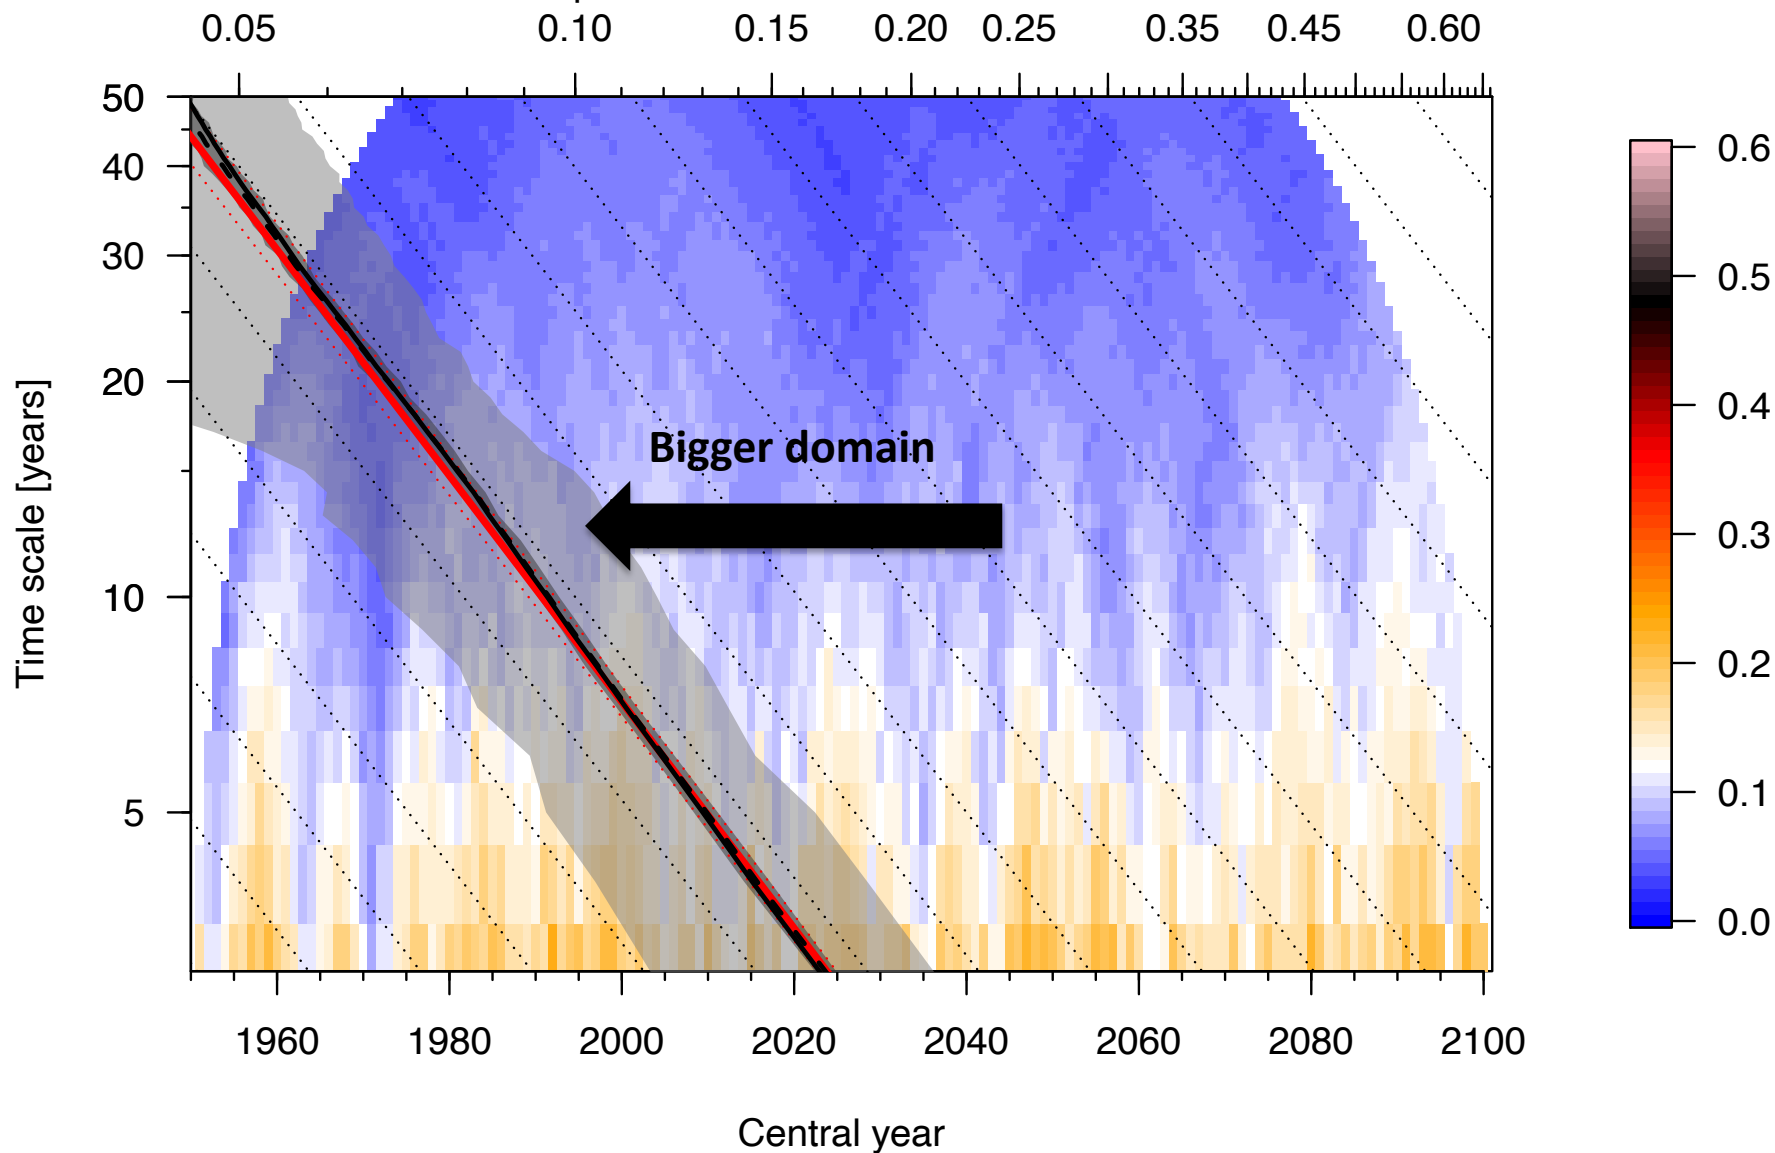

0.05 0.10 0.15 0.20 0.25 0.35 0.45 0.60

# Larger domain EUR

Internal variability for different time-scales  
DJF precip domain: EUR=SREX[NEU+CEU+MED]

computed as fraction of ensemble mean

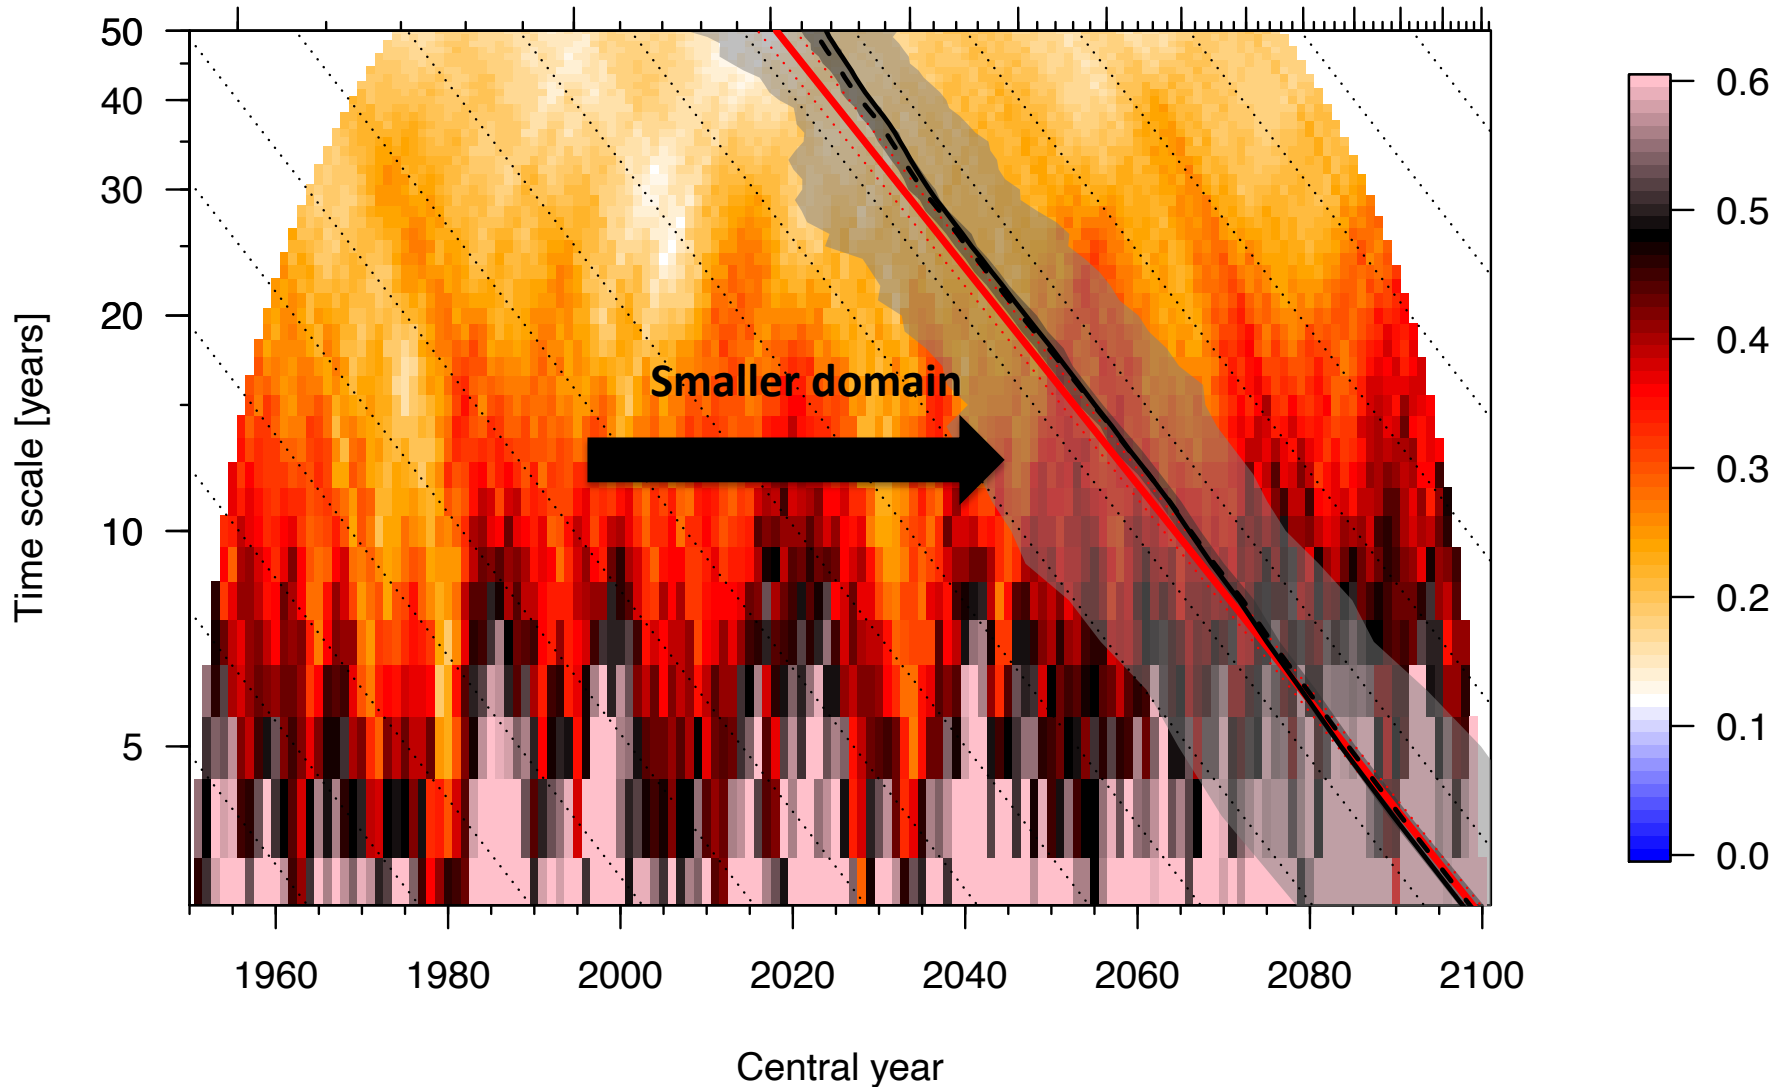

# Gridbox

## MAD

Internal variability for different time-scales  
DJF precip domain: MAD (Madrid,  $-3.75^{\circ}\text{E}$ ,  $41.25^{\circ}\text{N}$ )

computed as fraction of ensemble mean

0.05 0.10 0.15 0.20 0.25 0.35 0.45 0.60

# Can we get away with fewer members? (LOCAL)

Internal variability for different time-scales  
DJF precip domain: MAD (Madrid, -3.75E, 41.25N)

computed as fraction of ensemble mean

Central year

**5 members (#1-5)**

## MADRID

Internal variability for different time-scales  
DJF precip domain: MAD (Madrid, -3.75E, 41.25N)

computed as fraction of ensemble mean

**10 members (#1-10)**

Internal variability for different time-scales  
DJF precip domain: MAD (Madrid, -3.75E, 41.25N)

computed as fraction of ensemble mean

**All 16 members**

Short answer: Yes

# Can we get away with fewer members? (REGIONAL)

Internal variability for different time-scales  
DJF precip domain: SREX[MED]

**5 members (#1-5)**

Short answer: Yes

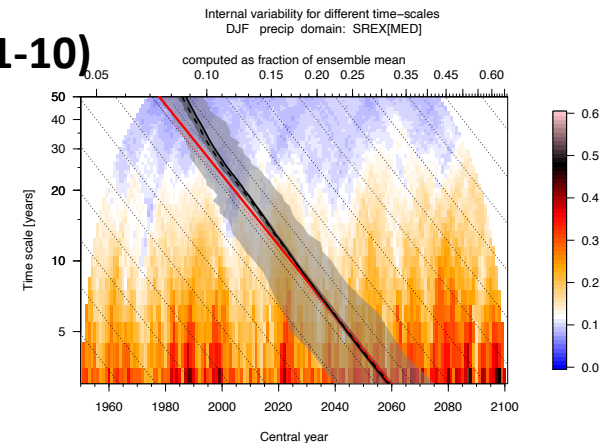

**MED**

Internal variability for different time-scales  
DJF precip domain: SREX[MED]

**10 members (#1-10)**

**All 16 members**

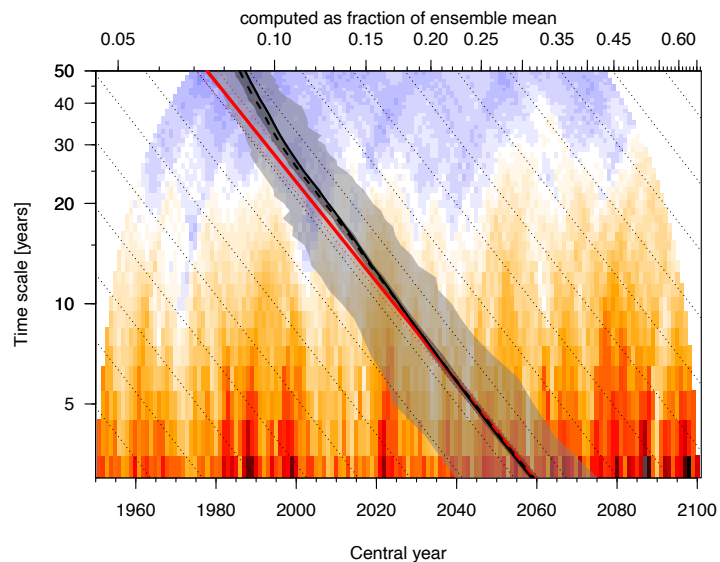

# Summary / Pros and cons

- Pros
  - Simple method using INT defined from ensemble spread.
  - The amplitude of INT can be predicted from an exponential fit using the fastest time scales (These you can estimate also in shorter simulations).
  - Makes clear how INT basically scales as random noise (see additional slides).
- Cons
  - Shown here are values relative to ensmean. Need to adjust when applying to e.g. temperature
  - The last step (aggregating over time) removes possible changes of INT over time. Only the (contour)-maps can show these
  - Assumes that we can determine the “forced signal” in another way (i.e. by loess regression). Usually it is the main aim to determine the forced signal, and here we assume we have it already.... => Ideally, you would compute the internal variability from a pre-industrial control simulation, but then we have no clue as to whether variability changes or not..

# MED (REGIONAL)

Internal variability for different time-scales  
DJF precip domain: SREX[MED]

## Seasonality

Internal variability for different time-scales  
MAM precip domain: SREX[MED]

DJF

MAM

JJA

SON

Internal variability for different time-scales  
JJA precip domain: SREX[MED]

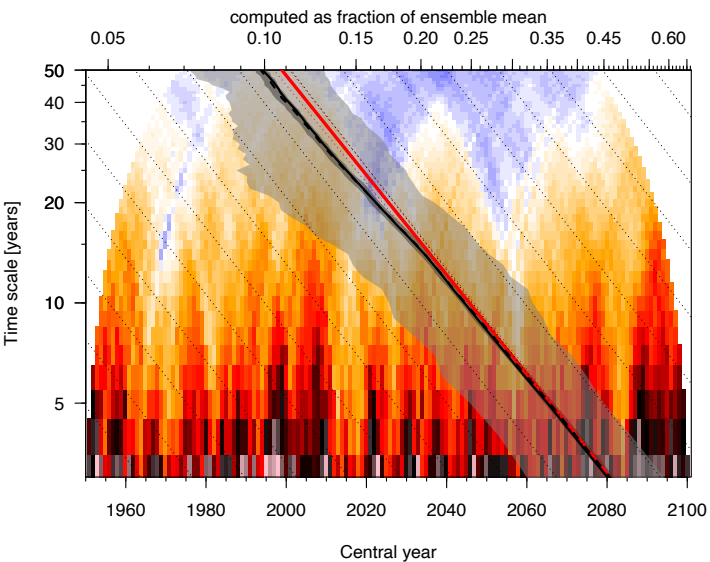

Internal variability for different time-scales  
SON precip domain: SREX[MED]

# DUS (LOCAL)

Internal variability for different time-scales  
DJF precip domain: DUS (Dusseldorf, 6.25E, 51.25N)

# Seasonality

Internal variability for different time-scales  
MAM precip domain: DUS (Dusseldorf, 6.25E, 51.25N)

DJF

MAM

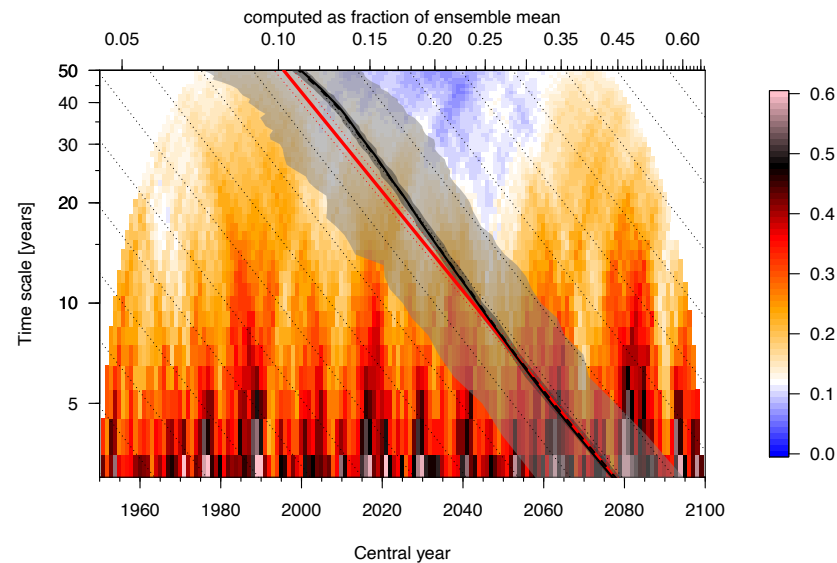

Internal variability for different time-scales  
JJA precip domain: DUS (Dusseldorf, 6.25E, 51.25N)

JJA

SON

Internal variability for different time-scales  
SON precip domain: DUS (Dusseldorf, 6.25E, 51.25N)

# Additional slides

But hey isn't this all familiar from white noise theory?

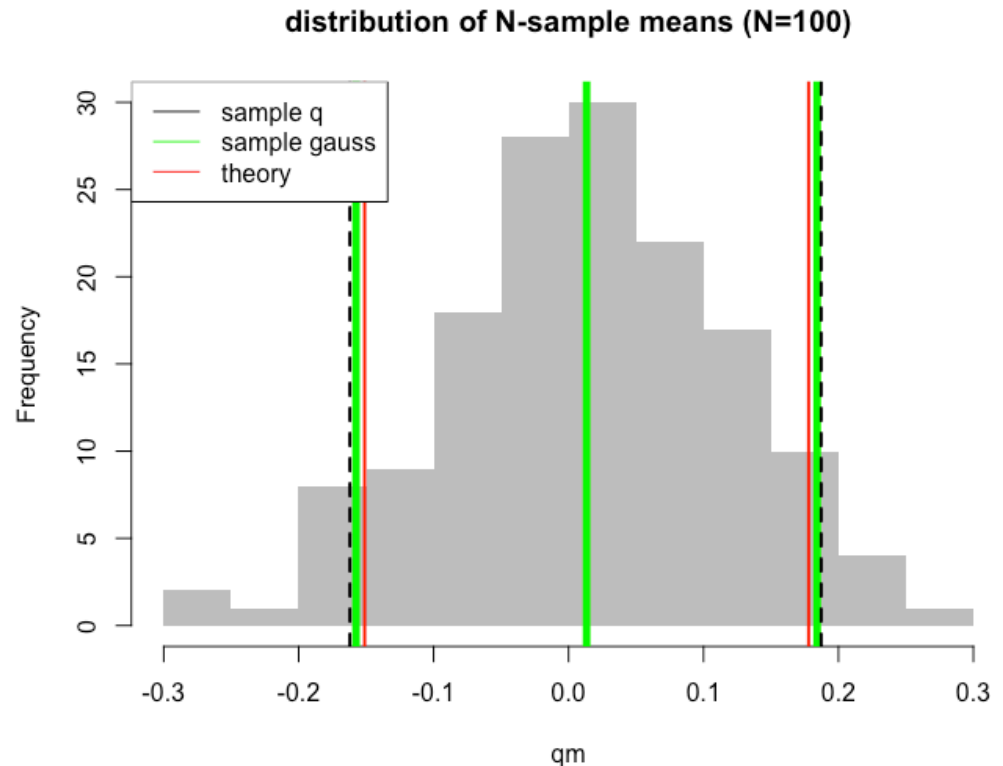

## Example: white noise

16 time series of white noise (surrogate for JJA precip for example) – offset for display only

# Example: white noise

- N-sample mean from normal distribution  $N(0,1)$
- The N-sample mean is distributed again normally, as  $N(0, sd)$
- where  $sd = 1/\sqrt{N}$

Example here,  $N_{mem}=100, N_{year}=150$

# Example: white noise

- N-Sample quantiles from normal distribution  $N(0,1)$
- The N-sample quantile is distributed again normally, as  $N(0, sd)$
- But now sd is more complex... **But still proportional to  $1/\sqrt{N}$**
- If p is quantile (0...1) then  $sd^2 = p(1-p)/f(p)^2$ , where  $f(p)$  is the density of that quantile given the distribution.

Example here, Nmem=100, Nyear=1000

# Example: white noise

- N-Sample **quantiles** from normal distribution  $N(0,1)$
- The N-sample quantile is distributed normally, as  $N(0, sd)$
- Now sd is more complex...  
**But still proportional to  $1/\sqrt{N}$**
- If  $p$  is quantile ( $0 \dots 1$ ) then  $sd^2 = p(1-p)/f(p)^2$ , where  $f(p)$  is the density of that quantile given the distribution.

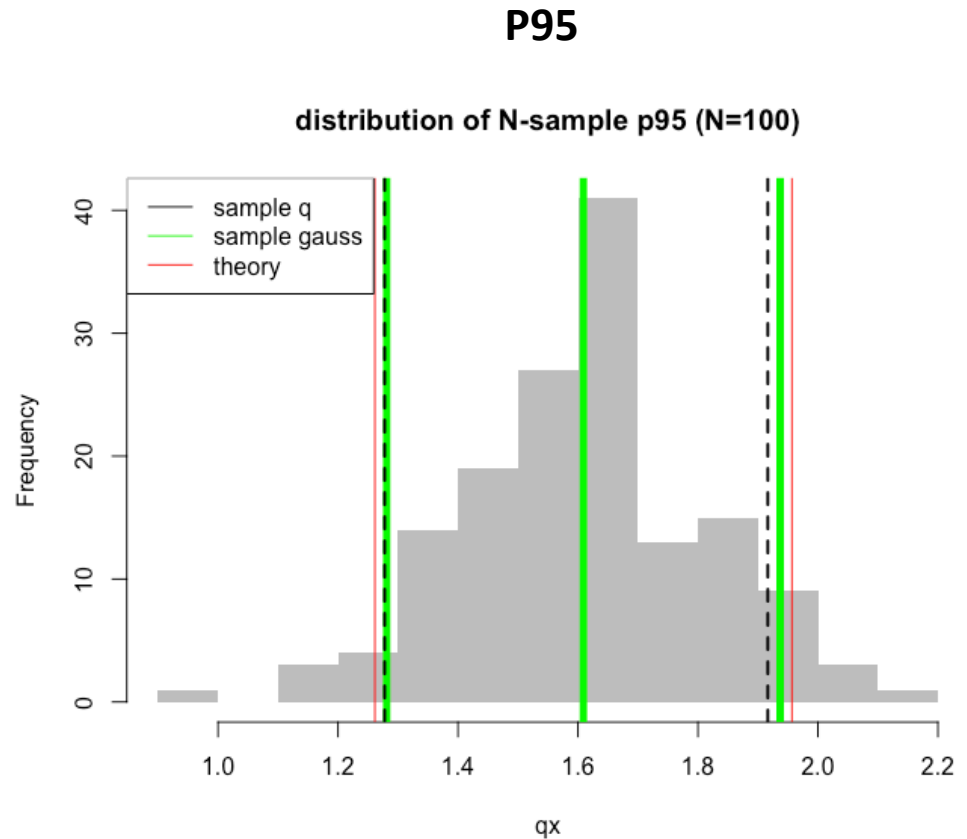

Example here,  $N_{mem}=100, N_{year}=1000$

Typically sd of sample-q gets broader for higher quantiles

# Example: white noise

- The **difference** of two normal distributions is again normally distributed, with
- $Z = Y - X \sim N(m_y - m_x, s_x^2 + s_y^2)$
- This implies that our n-sample measure of internal variability (P95-P05) is also distributed normally!

Example here, Nmem=100, Nyear=1000
