# Overview

## Motivations of the study:

- Maceió municipality is suffering **severe geological instability** related to mining activities near the cost of the Mundaú Lagoon;
- Fractures on both buildings and roads have intensified mainly in Pinheiro neighborhood since the beginning of 2018, especially after strong rainfall event on 15th of February 2018 and a seismic shock of local magnitude 2,4mR on 3rd of March 2018;
- Geodetic ground measurement are not available;
- Historic and updated geodetic InSAR measurements have not been provided yet.

## Our goals:

- Detect the **onset** of the instability;
- Track the **temporal and spatial evolution** of the instability;
- Estimate the **cumulative subsidence** rate;
- Estimate possible horizontal deformations;
- Have an overview understanding of the evolution of the **source of the subsidence**.

## Methods:

- **Multi-temporal DInSAR analysis** (SBAS technique) using multi-sensor SAR data from 10.2003 up to 03.2020;
- **Geophysical modelling** (Mogi and Okada) to model the evolution of the source;
- **2D geomechanical modelling** to simulate 2 real salt-cavities, their stages of instability and the possible future development evolution of the surface displacement.

# LOS Time-Series

# **Geophysical Modeling**

We have many active cavities which contribute to the subsidence, however in this study we assumed a unique source model. Salt mines are located in a depth between 700 and 1000 m and are all close to the Mundaú Lagoon.

### Okada model:

• We fixed the location with that from Mogi model;

rectangular source-opening 600x150m

- We considered horizontal plane (dip=0°);
- We fixed the plane size to 600x150m.

# 2D Geomechanical Modeling

2D distinct element method (DEM) was used to simulate the evolution of two real size cavity models. Four different geomechanical stages were simulated:

# Conclusions

#### Leibniz Universität Helmholtz-Zentrum Hannover

GFZ

## Regarding the subsidence phenomena:

- Already in 2004/2005 subsidence started to appear;
- It has intensified up to 23/24 cm/year since 2018; •
- A cumulative max. subsidence of 1.8 m was estimated from March 2015 to March 2020;
- A east-west horizontal motion is estimated up to 8/9 cm since 2018;
- Geophysical models show horizontally stable source, upward fracture propagation since **2016/17** and a clear volume change increment since 2016/17;
- Geomechanical models shows good agreement of the simulated subsidence with the DInSAR measurements and they also show upward fracture propagation;
- Based on the geomechanical modelling, in case of a total collapse of the two cavities, an • approximate further 1m of subsidence is expected to occur, though no sinkholes.

## **General conclusions:**

- InSAR is a **powerful tool to detect and monitor in time geological instabilities** especially in urban areas due to the higher coherence;
- The availability of archives of historical SAR data allows to obtain backdated geodetic • **measurements** and to contribute to understand the onset of geological instabilities;
- The very high temporal resolution and not commercial **Sentinel-1** data provides **very good** temporal displacement trend detection;
- The availability of both ascending and descending acquisitions allows also horizontal • **component** estimation, which cannot be neglected in urban areas;
- Geomechanical and geophysical modelling (this last based on DInSAR data) provide good overview understanding of the source time and space evolution.
