This study combines ground-based gas phase, particle, and rainfall measurements at the ATTO site to study the impact of rainfall events on greenhouse and reactive gas concentrations and discuss how this process is relevant for producing new particles. Measurements of CO<sub>2</sub>, CH<sub>4</sub>, CO, O<sub>3</sub>, NO, and NO<sub>2</sub> concentrations were collected from the surface to 79m using a tower at the ATTO site in the central Amazon forest northeast of Manaus, Brazil. Particle size distribution was measured by an SMPS and rainfall by a rain gauge at the top of the tower. Data collection started in 2012, and this analysis covered the period up to 2020. The 30-minute interval dataset was used to study how convective events modify the concentration of these gases. During the rainfall events, CO<sub>2</sub>, CO, and CH<sub>4</sub> concentrations decrease, though CH<sub>4</sub> varies less with height than CO and CO<sub>2</sub>. The daily cycle of NO<sub>2</sub> presents an interesting characteristic showing distinct daily evolution for the concentration in the upper and lower levels. The decrease in NO<sub>2</sub> concentration in the upper level and the increase near the surface in the afternoon, which is the typical time of rainfall events, indicate that a specific process occurs near the surface. With the joint analysis of gas-phase observations with ultrafine particles and rainfall data, it was possible to evaluate the interesting physical-chemical processes occurring during the rainfall events that might be important for particles nucleation. The time of rainfall events was defined as the first-time rain rate reaching 3 mm/hours, a typical value of the beginning of convective rainfall events. Interestingly, during rainfall events, there is a significant injection of O<sub>3</sub> above and inside the canopy, and at this moment, its concentrations can increase by 300%. At the same time, NO decreases, and NO<sub>2</sub> increases its concentration, suggesting a reaction between NO and O<sub>3</sub> forming NO<sub>2</sub>. The concentration of NO<sub>2</sub> follows the increase in particle concentration smaller than 20nm. This result opens new perspectives on the role of new particle formation related to rain and vertical mixing in the Amazon.
