Using a synoptic-regression based approach, this study estimates future maximum 8 hourly mean O<sub>3</sub> levels under the future A1B scenario for a rural background area situated in The Netherlands. The statistical downscaling tool was used to downscale the Atmospheric-Ocean Coupled General Circulation Model (AOGCM) ECHAM5-MPI/OM for the present-day 20 Century (20C) control run (1991-2000) and two future A1B scenario periods (2051-2060 and 2091-2100). First, the statistical downscaling tool is evaluated in terms of downscaled O<sub>3</sub> levels for the present-day climate, using a long record of observed O<sub>3</sub> concentrations. Afterwards, these findings are used to introduce a bias correction on future estimates of O<sub>3</sub> concentrations under a changing climate. For the future A1B scenario, overall O<sub>3</sub> levels could increase with 2.8 and 10.9  $\mu\text{g}/\text{m}^3$ , for the period 2051-2060 and 2091-2100 period respectively, against the present-day 10-year average of 54.1  $\mu\text{g}/\text{m}^3$ , with a more pronounced effect in summer. Together with the mean properties, the number of days with high levels ( $> 120 \mu\text{g}/\text{m}^3$ ) of O<sub>3</sub> could increase with 7.3 days yr<sup>-1</sup> and 20.7 days yr<sup>-1</sup> by the 2050s and 2090s respectively. Increase in summer O<sub>3</sub> levels are especially due to a decrease in cloud cover associated with an increase in shortwave downward radiation and an increase in maximum temperature. Hereby, the extreme summer of 2003 is shown to be an example of how future European summers (in terms of O<sub>3</sub>) may look like under a changing change. Next to that, some other issues are put forward to be considered in the prospects of future ozone projections and mitigation in Western and Central Europe.
